1. Introduction

CANDU reactor is one of the three major commercial power reactor design used throughout the world. For the heat transport system (HTS) of a CANDU reactor, inside the reactor core is 2.5 wt% Nb alloy pressure tubes and connect carbon steel pipes outside the core.

Corrosion of these pipes under reactor operating conditions is a main concern for aging CANDU reactors. Steel corrosion releases metal ions into the coolant, which can precipitate along the circuit, potentially affecting the heat transfer efficiency of the system. Their neutron activation prior to precipitation can increase radioactivity levels outside the reactor core, and pose a safety problem during reactor shutdown and maintenance. Various measures have been taken to minimize these effects, such as coolant purification and filtration and the adoption of pH control to minimize solubility. Concern about steel corrosion is not limited to CANDU, but also to PWR (pressurized water reactor) and BWR (boiling water reactors), although these reactors use stainless steel.

The corrosion of steels is strongly affected by the presence of oxide films, which vary considerably in reactivity and solubility. Generally, corrosion studies have been limited to the low corrosion potential range where carbon steel in de-aerated water is typically poised. In this potential range, the surface oxide film is considered to be mainly magnetite, Fe₃O₄ [1], but more recent studies on the synergistic interaction of water radiolysis and carbon steel corrosion [2] suggest that H₂O₂, produced by radiolysis, can increase the corrosion potential to a range where Fe(III) oxides, such as Fe₂O₃ and FeOOH, may also form in addition to Fe₃O₄. These surface oxides may interact with water radiolysis products very differently, making it difficult to predict the effect of radiation on steel corrosion, since H₂O₂ may disproportionate on the oxide-covered surfaces ($\text{H}_2\text{O}_2 = 2\text{O}_2 + \text{H}_2\text{O}$), as well as drive steel corrosion.

Our primary goal is to determine how radiolytic oxidants, such as H₂O₂, will interact with oxide-covered steel surfaces and what influence this will have in steel corrosion kinetics. However, oxide films formed on carbon steel are complex mixtures of several different iron oxides and oxyhydroxides, making the corrosion chemistry of steel notoriously complex. For example, lepidocrocite, γ -FeOOH, is a ubiquitous ferric oxyhydroxide that may enhance the rate of corrosion since it is suspected to act as an electron acceptor towards iron metal [3]. We have prepared single-phase oxide films on gold to facilitate electrochemical measurements on these oxides. By studying the behaviour of H₂O₂ on individual oxides/hydroxides we hope to be able to characterize the more complicated behaviour of carbon steel surfaces in the presence of radiolytically-decomposed water.

In this paper, we prepared single-phase γ -FeOOH on the gold electrode and characterized with electrochemical impedance spectroscopy (EIS). The H_2O_2 reaction with the oxide films was then followed by corrosion potential, E_{CORR} , and EIS measurements as a function of exposure time to H_2O_2 . Ex situ Raman spectroscopy were used to characterize the oxides/hydroxides films.

2. Experimental

2.1. Electrochemical system

A standard three-electrode cell, consisting of a gold working electrode, a reference electrode and a counter electrode, was used for all experiments. The working electrode was a 6-mm (in diameter) gold disc (goodfellows), set in resin so that only the flat front face was exposed to the solution. Prior to deposit film, this electrode was manually polished with 600 and 800 grit silicon carbide papers, and polishing residue removed by sonication in an acetone/methanol mixture for 5 min. The reference electrode was a saturated calomel electrode (SCE) and the counter electrode was platinum mesh. All potential measurements were made with, and are quoted against, a saturated calomel reference electrode (SCE).

A Solartron model 1240 potentiostat and 1252 frequency response analyzer were used in all electrochemical measurements. CorrwareTM and Corrview software (supplied by Scribner and Associates) was used to control experiments and analyze data. Electrochemical Impedance Spectroscopy (EIS) was performed by applying a 10 mV sinusoidal potential waveform at an open circuit potential over the frequency range 10 kHz to 10^{-2} Hz.

2.2. γ -FeOOH film preparation

The γ -FeOOH films were prepared following our previous work [4]. The gold electrodes were directly immersed 20 mmol/dm³ $\text{Fe}(\text{NO}_3)_3$ solution suspended vertically. The film deposition time in the oven was 24 h and the oven temperature ranged from 60°C. The electrodes were then removed from the solutions, rinsed with distilled water, and suspended in air to dry at ambient temperature for 24 h.

2.3. Solutions

Experiments were conducted at room temperature in Ar-purged 0.01 M borate ($\text{Na}_2\text{B}_4\text{O}_7$) with the pH adjusted to 10.6 with NaOH (unless otherwise stated). Solutions were prepared with water purified using a NANOpure Diamond UV ultrapure water system from Barnstead International to remove organic and inorganic impurities. Prepared in this manner, the water had a resistivity of 18.2 M Ω cm.

A hydrogen peroxide stock solution was prepared by adding an appropriate amount of concentrated H_2O_2 (3% in the weight percentage) to the electrolyte solution to bring the H_2O_2 concentration to a desired value in the range of 10^{-4} to 10^{-3} mol dm⁻³ (M).

2.4. Experimental procedure

The experimental procedure used to study the interaction of electrochemically grown oxide films with H_2O_2 is presented schematically in Fig. 1. The E_{CORR} of the oxide covered gold electrode was allowed to relax for ~ 60 min to a pseudo steady-state value (Step 1), and the electrode/solution interface characterized by EIS (Step 2). The reaction

of the oxide films with H_2O_2 was initiated by adding H_2O_2 to the electrolyte solution, to bring the H_2O_2 concentration to desire. The progress of the reaction was monitored by measuring E_{CORR} (Step 3), and recording EIS spectra at various reaction times (Step 4).

Fig. 1. Schematic of the experimental procedure used in this study.

2.5. Surface analysis

The Raman spectrum of the samples was measured using a Renishaw Ramascope Model 2000 (633 nm laser wavelength, approx. 2mW at the sample at 100% power, scan from 2000-120 cm^{-1}).

3. Results and discussion

3.1 Cyclic Voltammetry

Two voltammograms recorded at pH10.6 and room temperature are shown in Fig. 2. Scan from 0.2 V to -1.0 V and back to 0.2V.

For the $\gamma\text{-FeOOH}$ films before exposed to H_2O_2 , at cathodic scanning, current is very low in the range 0.2 ~ -0.5 V. When potential passes the -0.5 V, the current significantly increases, indicating reducing reactions occur. From equilibrium potentials and our prior to works [2, 5-7], the reducing reaction are $\gamma\text{-FeOOH}$ to Fe_3O_4 and then Fe_3O_4 to Fe(II) species. At anodic scanning, the current significantly increases due to H_2 absorbed at electrode surface during cathodic scanning is reduced. The peak at -0.6 V is assigned Fe(II) species oxidized, for example $\text{Fe}(\text{OH})_2$ to Fe_3O_4 . The peak at -0.4 V is Fe_3O_4 oxidized to $\gamma\text{-FeOOH}$.

For the $\gamma\text{-FeOOH}$ after exposed H_2O_2 12h, the voltammogram is slight different with before exposed to H_2O_2 indicating the $\gamma\text{-FeOOH}$ film no significant changed. In the cathodic scanning, at -0.4 V, an additional peak appears. Considering reducing reaction here, $\gamma\text{-FeOOH}$ to Fe_3O_4 is assigned [8]. Because crystalline sizes of FeOOH (partially) decrease due to interaction with H_2O_2 , the reducing reaction $\gamma\text{-FeOOH}$ to Fe_3O_4 occurs early (partially). Detail discussion is in following sections.

Fig. 2. Cyclic Voltammetry of γ -FeOOH films on gold electrodes in pH 10.6 borate solutions. Scan rates 5mV/s. Scan after exposed in H₂O₂ γ -FeOOH film in Ar-purged fresh pH10.6 borate solutions.

3.2 Electrochemical impedance spectroscopy

The EIS spectrum of γ -FeOOH before expose to H₂O₂ can be fitted by one time constant (not shown). The resistance is ~ 1.8 M Ω and capacitance is ~ 20 μ F. The resistance and capacitance are not change with time in pH 10.6 borate solution.

Fig. 3. The electrical equivalent circuit used in EIS analyses and Schematic representation of the γ -FeOOH film after exposed H₂O₂

Relaxing open circuit potential (OCP) of γ -FeOOH films in pH 10.6 borate solution, the OCP reaches steady-state after 1h. After adding H₂O₂ into the solution, the OCP immediately falls ~ 0.3 V and the impedance falls several orders comparing with the film impedance before expose to H₂O₂, indicating the films break down and form more pores.

Fig. 4. Film resistances and capacitances obtained by fitting to the electric equivalent circuit in [fig. 2](#): (a) upper figure, the outer layer; and (b) lower figure, the inner layer.

EIS equivalent circuit as [Fig. 3](#) shown has good fitting results for fitting $\gamma\text{-FeOOH}$ films interaction with H_2O_2 . It is consistent with film structure changing, namely, more pores formed in the films as shown at CV and OCP results.

In the equivalent circuit, R_s is bulk solution resistance. Q_1 is capacitance of film outer layer. R_1 is resistance of solution in the pores. R_2 is resistance of film inner layer. Q_2 is capacitance of film inner layer.

Fitting results of R_1 and Q_1 are shown in Fig. 4a, R_2 and Q_2 shown in Fig. 4b with various H_2O_2 concentration and reaction time. For the H_2O_2 concentration from $1 \times 10^{-4} M$ rising to $1 \times 10^{-3} M$, the Q_1 from $\sim 11 \mu F$ increases to $\sim 21 \mu F$.

From equation $C = A\epsilon_0\epsilon/L$, where A is the geometrical surface area, ϵ_0 is the permittivity of free space. ϵ is the oxide film dielectric constant. L is the passive layer thickness. Q_1 decreases following H_2O_2 concentration rising, indicating the outer layer thickness in higher concentration H_2O_2 is thinner than that in the lower H_2O_2 concentration. Similar trend can be found for Q_2 . Q_2 decreases following H_2O_2 concentration rising, indicating the inner layer thickness in higher concentration H_2O_2 is thinner than that in the lower H_2O_2 concentration.

R_1 increases following H_2O_2 concentrations rising, indicating the pore volumes increasing with rising H_2O_2 concentrations.

R_2 decreases along with H_2O_2 concentration, indicating inner layer is thinner in higher H_2O_2 concentration, being consistent with Q_2 .

At lower concentration H_2O_2 , $1 \times 10^{-4} M$, Q_1 decreases with reaction time, indicating outer layer thickness increasing due to redeposition $FeOOH$ on the surface [2]. Redeposition thickness is not too much because Q_1 is just small change. Q_2 is similar trend and increase significantly several orders indicating inner layer thickness increases much with reaction time. Redeposition effects is very significant in inner layer due to small pore volumes. In the small pore volume, soluble $Fe(III)$ species cannot easily diffuse to the bulk solution. Therefore, when H_2O_2 is exhausted in the pore, the $Fe(III)$ species (partially) redeposit on the inner layer.

R_1 and R_2 in $1 \times 10^{-4} M$ H_2O_2 increase with time, indicating pore volumes reducing and inner layer thicker with time, due to redeposition, being consistent with Q_2 capacitance results.

At H_2O_2 concentration $5 \times 10^{-4} M$, H_2O_2 effect is similar as $1 \times 10^{-4} M$. However, effect is enhanced due to higher H_2O_2 concentration.

At H_2O_2 concentration $1 \times 10^{-3} M$, R_1 , R_2 , Q_1 , Q_2 just slightly change with reaction time. Because at higher H_2O_2 concentration, films form more pores and pore volumes are larger. Soluble $Fe(III)$ species easily to diffuse into the bulk solution, therefore, redeposit effect is not significant.

3.3. Raman spectra

Fig. 5. shows Raman spectra of single-phase γ - $FeOOH$ and after exposed to H_2O_2 $1 \times 10^{-3} M$ 12h. After exposed to H_2O_2 $1 \times 10^{-3} M$ 12h, all Raman peaks of the films are exactly match with single-phase γ - $FeOOH$ peaks, suggesting the γ - $FeOOH$ film composition does not change after interaction with H_2O_2 . However, after exposed to H_2O_2 , peak intensity slight reduces indicating film microcrystalline change to smaller, which are consistent with analysis of CV and EIS.

Fig. 5. Ex situ raman spectra of γ -FeOOH films: the upper spectrum is for a film not exposed to H_2O_2 while the lower spectrum is for a film exposed to $1 \times 10^{-3} \text{M}$ H_2O_2 .

4. Conclusion

CV, EIS and Raman spectra confirm the γ -FeOOH films composition does not appear to alter before or after exposed to H_2O_2 . H_2O_2 interacts with FeOOH films resulting film break down and/or more pores formed. Furthermore, the γ -FeOOH films form two layers, porous outer layer and inner layer. The pores formed at lower concentration H_2O_2 have small volume. FeOOH redeposition occurs and makes pore volumes reduce, therefore, thickening inner layers and recover the films. Higher H_2O_2 concentration makes FeOOH films to form larger volume pores and redeposition does not significantly appear.
